## Section 1.4

Precipitation

The precipitation data used in this report were measured by a Bendix-Friez self-recording, weighing-type rain gage from January 1, 1950 until August 7, 1960, and by a Bendix-Friez tipping bucket precipitation gage for the remainder of the period. After August 7, 1960, the weighing gage was continued in operation and used both as a check on and as a substitute for the tipping bucket when the latter was inoperative. A standard 8-inch U.S. Weather Bureau rain gage has been used as an additional check on the precipitation measurements. Both the weighing and tipping bucket gages are unshielded and are located in an open field about 20 feet apart.

Since the meteorology station is manned only from 0830 to 1700 local time, Monday through Friday, snow data are incomplete. No analyses based on snow are presented. Precipitation amounts which were less than 0.01 inches were recorded as a "trace" of precipitation. An hourly observation of precipitation represents the total amount of precipitation which fell in the preceding hour.

1.4.1. Precipitation Amounts

Table 159. Monthly Precipitation Amounts in Inches for Each Year.  
January 1950–December 1964.

This table gives the amount of precipitation measured during each month and year. The total amount for each year is listed in the column labeled "annual." The monthly average amount of precipitation is listed in the row labeled "mean." It is quite evident from these data that substantially larger amounts of precipitation occur in the spring and summer. Trace amounts are not included in these data.

Figure 43. Monthly Precipitation Amounts in Inches for Each Year.  
January 1950–December 1964.

This figure is based on the data of Table 159. The salient features of this figure are the variability of precipitation amounts from month to month and the occurrence of larger values in summer than in winter. Strikingly, there are the anomalous rainfall amounts which occurred in October 1954, and September 1961. In both cases over 13 inches of rain fell.

Table 160. Frequency Distribution of the Daily Amounts of Precipitation in Inches. January 1950–December 1964.

Table entries are the number of days in each month with the specified amounts of precipitation. For example, the total number of days with

precipitation amounts of 0.01 to 0.04 inches for the 15 Januaries is 43. The "total" column indicates that on about 30 percent of all days more than a trace was recorded in at least one hour.

Table 161. Monthly Maximum of Daily Amounts of Precipitation in Inches with Day of Occurrence. January 1950–December 1964.

This table gives the maximum daily amount of precipitation in inches measured within the specified month and year and its date of occurrence. The column labeled "annual" contains the maximum daily precipitation amounts for each year.

Table 162. Maximum Precipitation in Inches for Specified Time Intervals. January 1950–December 1964.

This table gives the maximum amount of precipitation measured within the specified time periods of 1, 2, 3, 6, 12, 36 and 48 hours. In determining the entries for this table all combinations of consecutive hours of specified length were examined and the date of the first hour of the first time period containing the maximum precipitation amount was chosen as the date of occurrence.

#### 1.4.2. Frequency of Precipitation and No Precipitation

Table 163. Monthly Number of Hours of Precipitation for Each Year. January 1950–December 1964.

The table entries are the number of hours in each month and year during which precipitation including traces occurred. The column labeled "total" contains the total number of hours with precipitation for each year.

Figure 44. Monthly Number of Hours of Precipitation for Each Year. January 1950–December 1964.

This graph illustrates the data contained in Table 163.

Table 164. Number of Days during which Precipitation Amounts Equalled or Exceeded Specified Values for Each Year. January 1950–December 1964.

This table presents for each year the number of days in each month on which precipitation amounts equalled or exceeded the indicated values. The total number of days for each month on which precipitation amounts were greater than or equal to 0.01 inches are listed in the last column.

Table 165. Frequency Distribution of the Number of Consecutive Hours with Precipitation. January 1950–December 1964.

Table entries are the number of precipitation periods of the indicated duration for each month. An observation recorded as trace was counted as an hour of precipitation. To illustrate a table entry, the number of times that precipitation was recorded for a period of exactly five consecutive hours in the 15 Januaries is given as 17. A precipitation period which began in one month and ended in the next was counted with the data of the month in which it began.

Table 166. Frequency Distribution of the Number of Consecutive Days with Precipitation. January 1950-December 1964.

Table 167. Frequency Distribution of the Number of Consecutive Hours without Precipitation. January 1950-December 1964.

Table 168. Frequency Distribution of the Number of Consecutive Days without Precipitation. January 1950-December 1964.

These tables are constructed like Table 165 with the variable changed as indicated by the table titles. These tables and Table 165 provide information useful for scheduling projects that are dependent on the occurrence of precipitation.

## Section 1.5

Stability

The difference in air temperature between two levels above ground is a measure of thermodynamic atmospheric stability. From July 1, 1951, to August 5, 1952, a pair of thermopiles consisting of 5 copper-constantan thermocouples was used to obtain the temperature difference between 3.5 and 144 feet. On August 6, 1952, the lower thermopile was raised to 5.5 feet.

On July 1, 1961, additional temperature sensors, installed at 15.2, 34.0 and 72.2 feet, commenced operation. At this time the circuit was modified to allow measurement of the temperature difference through the use of a single copper-constantan thermocouple located at each level.

The lower thermal sensors (5.5 or 3.5 feet) are mounted on a horizontal aluminum boom support by an adjustable mast set at 5.5 (3.5) feet above ground level about 150 feet west of the Meteorology Tower as shown in Figure 2 of Appendix II. The other thermal sensors are mounted on aluminum booms extending horizontally from the Meteorology Tower. Temperature difference measurements for the period July 1, 1951, to December 1, 1960, were recorded on a Honeywell Electronik Potentiometer recorder and read to the nearest tenth of a degree Celsius. Before November 30, 1956, an averaging interval of 10 minutes was used. After this date the temperature difference measurements were averaged for two minutes. Starting January 1, 1964, the data processing system which automatically computes the 2-minute average by means of a Librascope "ball and disc" integrator provided the data. The temperature difference values recorded in degrees Celsius were converted to degrees Fahrenheit.

Temperature difference values during hours of precipitation were considered missing because of errors due to moisture effects on the sensors. This accounts for a major fraction of the missing data. It is likely that during precipitation the vertical temperature gradient approximates the wet adiabatic lapse rate. The omission of these data, therefore, creates a bias.

Only 144- minus 5.5-foot and 15.2- minus 5.5-foot temperature differences are used in this report.

Tables 169 through 181: Percentage Frequency and Mean of 15.2- minus 5.5-foot and 144- minus 5.5-foot Temperature Difference (°F) for Each Hour of the Day. Monthly and Total Period. July 1951-December 1964 (144- minus 5.5-foot). January 1961-December 1964 (15.2- minus 5.5-foot).

These tables present the percentage frequency of occurrence of temperature difference within the indicated intervals for each hour. The column labeled "mean" contains the average of the temperature difference observations for each hour. According to these data, strong inversions rarely, if ever, occur during the early and late afternoon and strong lapse conditions are rare during the dark hours. In 39% of the cases, the temperature was increasing with height between the 144- and 5.5-foot levels.

## Section 1.6

### Direct and Diffuse Solar Radiation

Since September 1950, a 50-junction Eppley pyranometer mounted 6 feet above ground was used to obtain measurements of the intensity of solar and sky radiation received on a horizontal surface. These data were recorded on a Leeds and Northrup Micromax recorder in Langleys ( $\text{g-cal/cm}^2$ ) per minute. Prior to September 1, 1960, 20-minute averages of solar radiation for the first, second and third 20-minute intervals of each hour were obtained by the "equal area" method from the recorder charts. These averages were used to compute the total radiation received within the hour. After September 1, 1960, the total radiation received for the hour was obtained by means of a Librascope "ball and disc" integrator used as a component of the automatic data processing system.<sup>2</sup> Hourly amounts of solar radiation are recorded to the nearest tenth of a Langley for the time period 0400 CST to 2000 CST each day. The factory and Weather Bureau calibrations of the pyranometer were assumed to be correct and to remain constant; no calibration was made at this station. The glass on the instrument is cleaned daily.

During the spring and fall of the year the Meteorology Smoke Stack, which has a diameter of 18 inches and is located 155 feet east of the pyranometer (see Figure 2 of Appendix II), causes a shadow effect to occur. This error in the hourly totals was small enough to be neglected.

#### 1.6.1. Daily Totals of Solar Radiation

Table 182. Monthly Maximum of Daily Totals of Solar Radiation on a Horizontal Surface in Langleys during the Hours 0400-2000 CST. September 1950-December 1964.

This table gives the maximum of daily totals of direct and diffuse solar radiation for each month and year. A blank in the table indicates that no data are available for the month. A daily total was considered missing if one hourly observation in the hours 0500 through 2000 CST was missing.

Table 183. Monthly Mean of Daily Totals of Solar Radiation on a Horizontal Surface in Langleys during the Hours 0400-2000 CST. September 1950-December 1964.

Table entries are the mean monthly values of daily totals of direct and diffuse solar radiation in Langleys. A blank indicates missing data. The average daily total based on the entire period is 348 Langleys.

Table 184. Monthly Minimum of Daily Totals of Solar Radiation on a Horizontal Surface in Langleys during the Hours 0400-2000 CST. September 1950-December 1964.

This table is constructed like Table 183 but presents the minimum of daily totals of solar radiation.

Figure 45. Maximum, Minimum and Mean of Daily Totals of Solar Radiation on a Horizontal Surface in Langley during the Hours 0400-2000 CST. September 1950-December 1964.

This figure is a graphical presentation of the data in Tables 182 through 184.

Figure 46. Percentile Distribution of Daily Totals of Solar Radiation on a Horizontal Surface in Langley during the Hours 0400-2000 CST. September 1950-December 1964.

This figure presents the 10-, 25-, 50-, 75- and 90-percentile values and mean of the daily totals of direct and diffuse solar radiation.

Table 185. Percentile Distribution of Daily Totals of Solar Radiation on a Horizontal Surface in Langley during the Hours 0400-2000 CST. September 1950-December 1964.

This table gives for each month and year the 10-, 25-, 50-, 75- and 90-percentile values of the daily totals of direct or diffuse solar radiation.

#### 1.6.2. Hourly Totals of Solar Radiation

Table 186. Average Hourly Solar Radiation on a Horizontal Surface in Langley. September 1950-December 1964.

This table presents the mean of the direct and diffuse solar and sky radiation measured each hour of each month.

Figure 47. Percentile Distribution of Hourly Amounts of Solar Radiation on a Horizontal Surface in Langley. September 1950-December 1964.

This figure shows the "annual march" of the hourly solar radiation pattern. The 10-, 25-, 50-, 75- and 90-percentile curves of hourly totals of solar radiation are presented.

Table 182. Monthly Maximum of Daily Totals of Solar Radiation on a Horizontal Surface in Langleys during the Hours 0400-2000 CST. September 1950-December 1964

Figure 47. Percentile Distribution of Hourly Amounts of Solar Radiation on a Horizontal Surface in Langleys. September 1950–December 1964

## Section 1.7

### Net Radiation

A Beckman and Whitely Net Radiometer mounted on top of a 6-foot pole and a Honeywell Recorder were used to measure and record net radiation beginning on June 1, 1956 to the present. The location of the pole, shown in Figure 2 of Appendix II, is in a grass field at the Meteorology Site. This instrument is designed to measure the net flux of solar, sky, and terrestrial radiation near the surface. The magnitude of the net radiation flux directed downward is a measure of the amount of heat per unit area available to heat the earth's surface and air in contact with the surface, to evaporate soil and surface water (dew), and to support photosynthesis. Similarly, the magnitude of net radiation flux directed upward is a measure of the heat lost by the earth's surface.

Atmospheric radiation can be split into two classes by wavelength: short (0.29 to 4.0 microns) solar wavelengths and much longer infrared wavelengths (4 to 70 microns) associated with bodies at terrestrial temperatures. The downward flux of radiation includes both solar energy arriving as direct rays, energy scattered from dust, air and water vapor molecules, as well as energy reflected from and transmitted through clouds. The downward flux also contains infrared radiation emitted by clouds, water vapor, ozone and carbon dioxide.

The upward flux measured by this instrument includes reflected solar radiation plus long-wave radiation emitted from the surface.

Hourly measurements of radiation were read to the nearest tenth of a Langley ( $\text{g-cal}/\text{cm}^2$ ) and represent the total net radiation received during the hour preceding the time of measurement. Net radiation values were obtained from the pen and ink traces from June 1, 1956, to August 7, 1960. The equal area method was used to obtain 20-minute averages which were combined to obtain a 1-hour total. Beginning on August 8, 1960, the hourly totals were recorded automatically by the data processing system.

During the sunlit portion of the day, the net radiation is primarily positive, i.e., the net amount of radiation is directed toward the earth. During the dark hours the radiation flux is directed away from the earth.

When the sensing element of the radiometer becomes wet because of fog or precipitation, spurious readings result, and the net radiation data are considered missing. The following tables are, therefore, representative of nonprecipitation conditions.

**Table 187. Average Hourly Net Radiation on a Horizontal Surface in Langleys. June 1956–December 1964.**

Table entries are average hourly totals of net radiation for each month. The maximum average hourly net radiation occurs at about noon in all seasons and the minimum occurs just after sunset.

Table 188. Mean Daily Totals of Net Radiation on a Horizontal Surface in Langleys during the Hours 0400-2000 CST. June 1956-December 1964.

Table 189. Mean Daily Totals of Net Radiation on a Horizontal Surface in Langleys during the Hours 2100-0300 CST. June 1956-December 1964.

Table 190. Maximum Daily Totals of Net Radiation on a Horizontal Surface in Langleys during the Hours 0400-2000 CST. June 1956-December 1964.

Table 191. Maximum Daily Totals of Net Radiation on a Horizontal Surface in Langleys during the Hours 2100-0300 CST. June 1956-December 1964.

Table 192. Minimum Daily Totals of Net Radiation on a Horizontal Surface in Langleys during the Hours 0400-2000 CST. June 1956-December 1964.

Table 193. Minimum Daily Totals of Net Radiation on a Horizontal Surface in Langleys during the Hours 2100-0300 CST. June 1956-December 1964.

Tables 188 and 189 give the average of the daily totals of net radiation measured within the indicated time periods for each month and year. During the hours 0400-2000 CST the values are positive with the exception of a few in December and January. Highest values of incoming net radiation occur in June and lowest in December. In the dark hours 2100-0300 CST the mean values are negative, indicating net outgoing radiation, and the difference between summer and winter is very small. The annual mean values show appreciable variability for the eight years of record and range from 153.5 to 202.5 Langleys in the daytime and from -31.7 to -26.5 during the night hours. Tables 190 and 191 show the maximum daily totals of net radiation for the daytime and nighttime hours, and Tables 192 and 193 show the minimum daily totals for the same time periods.

Figure 48. Percentile Distribution of Hourly Amounts of Net Radiation on a Horizontal Surface in Langleys. June 1956-December 1964.

This graph illustrates the 10-, 25-, 50-, 75- and 90-percentile values of hourly amounts of net radiation for each month and year.

Figure 48. Percentile Distribution of Hourly Amounts of Net Radiation on a Horizontal Surface in Langleys.  
June 1956–December 1964

## Section 1.8

Atmospheric Pressure

A Bendix-Friez microbarograph located in the Meteorology Building was used to measure atmospheric pressure. The pressure readings obtained from the 7-day chart trace of the microbarograph represent time averages taken over a period of several minutes because of the response time of the instrument. The barograph was checked each week with a mercurial barometer, the ivory point of which is 746 feet above sea level. Hourly readings to the nearest 0.01 inch of mercury were made. Calibration corrections and time corrections were distributed proportionately over 7 days of the chart record.

1.8.1. Maximum, Minimum and Mean Station Pressure

Table 194. Maximum Station Pressure in Inches of Mercury.  
January 1950-December 1964.

Table 195. Mean Station Pressure in Inches of Mercury.  
January 1950-December 1964.

Table 196. Minimum Station Pressure in Inches of Mercury.  
January 1950-December 1964.

These tables present the maximum, mean and minimum atmospheric pressure in inches of mercury for each month and year. Tables 194 and 196 show that the highest maximum and lowest minimum occurred in the cold months. The highest pressure recorded was 30.04 inches and the lowest 28.16 inches, a range of 1.88 inches. The highest average monthly pressures generally occur in fall and winter and the lowest in spring.

Figure 49. Mean Station Pressure in Inches of Mercury for Each Month and Year. Presents the data of Table 195 in graphical form.

1.8.2. Range of Station Pressure

Information on atmospheric pressure change is needed in the atomic energy industry for the evaluation of hazards where leakage from a reactor building is of concern since the magnitude and nature of pressure changes determine how much radioactive material is released. The atmospheric pressure at a station undergoes change for a number of reasons. The most important is the passage of the large scale pressure systems - highs and lows. Smaller scale systems such as thunderstorms, squall lines and convective showers also produce pressure changes. Superimposed on all of these is the semidiurnal pressure wave, that is, an oscillation with a 12-hour periodicity. Tables 197-208 present range data based on the absolute daily extremes; Table 209 is based on hourly observations.

Table 197. Daily Maximum Pressure Range in Inches of Mercury.  
January 1950–December 1964.

Table 205. 3-day Minimum Pressure Range in Inches of Mercury.  
January 1950–December 1964.

Table 206. 7-day Maximum Pressure Range in Inches of Mercury.  
January 1950–December 1964.

Table 207. 7-day Mean Pressure Range in Inches of Mercury.  
January 1950–December 1964.

Table 208. 7-day Minimum Pressure Range in Inches of Mercury.  
January 1950–December 1964.

The daily pressure ranges were calculated by subtracting the daily minimum from the daily maximum pressure. Similarly, the 2-, 3- and 7-day ranges are the differences between the largest daily maximum and smallest daily minimum pressure in 2-, 3- or 7-consecutive-day periods. When the range period extended from one month or year into the next, the range was considered with the month and year in which it began.

The general pattern shown by all of these tables is that the maximum and mean pressure ranges are largest in the colder months and the minima are smallest in the summer. These tables, similar to all tables in this

publication, can be used to construct figures or charts by which intermediate values may be interpolated. The basic data are presented here and can be analyzed in various forms.

Table 209. Percentage Frequency Distribution of 2-hour, 11-hour and 23-hour Range of Station Pressure in Inches of Mercury Beginning with Indicated Hour. Total Period. January 1950-December 1964.

This table presents the percentage frequency distribution of 2-hour, 11-hour and 23-hour range of pressure. The 2-hour range distribution shows that in 93 percent of the cases, the change in pressure is less than 0.06 inches in 2 hours. The 50-percentile values for the 11- and 23-hour range distributions are in the 0.08-to 0.09-inch and 0.15- to 0.19-inch intervals, respectively.

## Section 1.9

Soil Temperature

Soil temperatures were measured with Leeds and Northrup 100-ohm copper resistance thermometers (Thermohms) located 1, 10, 20, 50, 100, 305 (10 feet), and 884 cm (29 feet) below a pasture-type plant surface. This plant cover was mowed periodically during the growing season. Measurements began on November 5, 1952; however, only data since January 1, 1953 have been used in this report. On March 3, 1953, the sensor at 29 feet failed because of a break in the circuit below ground level and remained inoperative until July 17, 1953, when it was replaced approximately 18 feet northeast of the original site. The location of these sensors is indicated in Figure 2 of Appendix II. The soil temperatures are recorded sequentially by a stepping switch on a single-pen Leeds and Northrup Micromax Recorder. A soil temperature sounding, i.e., a sequence of soil temperature readings beginning at 1 cm and progressing to 29 feet, is made twice each hour. Each sounding takes 30 minutes to complete. Temperatures at 50 cm, 100 cm, 10 feet, and 29 feet are recorded once each cycle; the others are read several times. Only the values measured closest to the hour were used in this report. A reference signal is used to indicate drift, if any, in the recording system.

Originally, soil temperatures were read from the strip charts to the nearest tenth of a degree Celsius. Since September 1957, the automatic data processing system<sup>2</sup> has been used to convert the sensor output into temperature values, again to the nearest tenth degree Celsius. All soil temperatures in this report are expressed in degrees Fahrenheit.

Tables 210 through 213. Average Hourly Soil Temperature (°F).  
January 1953–December 1964.

Each table entry is the average value for the indicated hour and month for the entire 12 years of record. The diurnal temperature cycle in the soil is the result primarily of the diurnal cycle of net radiation, modified by many other factors such as phase change of water (dew, frost and evaporation), insulating effect of a snow cover (when present), plant cover, advection, and rainfall. The maximum average 1-cm soil temperature usually occurs at 1300 or 1400 °C, the minimum at sunrise.

In the winter, when the soil is usually frozen and often covered with snow, the amplitude of the temperature cycle is very small at all levels. During the rest of the year, the amplitude of the cycle decreases with depth, and the time of extremes is retarded. At 50 cm in midsummer, the lowest temperatures occur at midday and the highest near midnight or early morning; that is, a nearly 180° phase shift has occurred in the temperature wave. The daily cycle is not perceptible at or below 100 cm.

Table 214. Annual Average Soil Temperature ( $^{\circ}$ F) at Each Depth.  
January 1953–December 1964.

The annual average temperatures show a sharp decrease from the 1- to the 10-cm level and remain almost unchanged below. The data also show a year-to-year temperature variability still exists even at 29 feet. A steady cooling of the upper soil layers persisted for 10 years, followed by two warmer years. This pattern is reflected at 10 and 29 feet.

Tables 215 and 216. Monthly Average Number of Hours per Year of Soil Temperature ( $^{\circ}$ F) Equal to or Greater than Indicated. January 1953–December 1964.

Table 217. Monthly Average Number of Hours per Year of Soil Temperature ( $^{\circ}$ F) Less than Indicated. January 1953–December 1964.

No rounding of temperature values was used in these tables. Certain values in these tables are phenologically significant, as soil temperature controls the germination of the seed, and to a lesser degree, plant growth. In the 12 years of record, no temperature equal to or below  $32.3^{\circ}$ F was observed at 100 cm or below, i.e., the soil was not frozen within this period at this level. No values of  $45^{\circ}$ F or less were observed at 29 feet.

Figure 50. Monthly Maximum, Average Maximum, Average, Average Minimum, Minimum and Average Daily Range of Soil Temperature ( $^{\circ}$ F).  
January 1953–December 1964.

The daily maximum and minimum values are the highest and lowest of the hourly observations for the day. The daily range is the difference between the daily maximum and minimum. This figure contains a graph for each depth. Plotted on each graph are six curves which are from top to bottom: the maximum of the hourly soil temperatures for each month, the monthly average of the daily maximum soil temperatures, the monthly average of hourly soil temperatures, the monthly average of the daily minimum soil temperatures, the minimum of the hourly soil temperature for each month, and the monthly average of the daily range of soil temperature.

Figures 51 and 52. Average Monthly Soil Temperature ( $^{\circ}$ F) at Each Depth for Each Year. January 1953–December 1964.

These curves show the variation with depth of phase and amplitude of soil temperature for each year. During the fall and winter months of some years, the average monthly values at the 1- and 10-cm levels are sufficiently close to make the curves indistinguishable.

The amplitude of the annual wave decreases with depth, and the time of extremes is retarded. At the 29-foot level the phase shift results in a reversal of seasonal air temperatures; that is, the highest temperatures occur in winter and the lowest in summer.

Figure 53. Annual Maximum, Minimum, Average, and Extreme Range of Soil Temperature ( $^{\circ}$ F) at Each Depth. January 1953-December 1964.

This figure contains a graph for each year. Plotted on each graph and appropriately labeled are four curves: (1) the annual maximum of the hourly soil temperatures, (2) the annual minimum of the hourly soil temperatures, (3) the annual average of the hourly soil temperatures, (4) the difference between the annual maximum and annual minimum soil temperature.

Table 210. Average Hourly Soil Temperature (°F).  
January 1953–December 1964
